Abstract

We have developed a Monte Carlo event generator for non-resonant diphoton ($\gamma\gamma$) production at hadron collisions in the framework of GR@PPA, which consistently includes additional one-jet production. The jet-matching method developed for initial-state jet production has been extended to the final state in order to regularize the final-state QED divergence in the $qg \rightarrow \gamma\gamma + q$ process. A QCD/QED-mixed parton shower (PS) has been developed to complete the matching. The PS has the capability of enforcing hard-photon radiation, and small- Q^2 photon radiations that are not covered by the PS are supplemented by using a fragmentation function. The generated events can be passed to general-purpose event generators in order to perform the simulations down to the hadron level. Thus, we can simulate the isolation requirements that must be applied in experiments at the hadron level. The simulation results are in reasonable agreement with the predictions from RESBOS and DIPHOX. The simulated hadron-level events can be further fed to detector simulations in order to investigate the detailed performance of experiments.

1 Introduction

Diphoton ($\gamma\gamma$) production is one of the most promising channels for the discovery of the Higgs boson having a relatively small invariant mass ($\lesssim 140 \text{ GeV}/c^2$) at the CERN LHC. However, the measurements suffer from the large irreducible diphoton background produced by non-resonant electromagnetic (QED) interactions [1, 2]. It is necessary to understand the properties of this background, not only for the search for the Higgs boson but also for detailed studies after the discovery. A precise understanding cannot be achieved without detailed knowledge of the photon-identification capabilities of experiments. In hadron-collision experiments, photon identification is influenced by soft hadrons that are additionally produced by various soft phenomena, such as initial- and final-state radiations, hadronization, decays, underlying events and event pile-ups, because a certain isolation condition has to be required in order to reduce the large contamination of π^0 from hadron jets. The effects of such soft phenomena cannot be reliably evaluated by analytical calculations or parton-level simulations. Hence, it is strongly desired to provide theoretical predictions in the form of Monte Carlo (MC) event generators with which we can carry out simulations down to the hadron level.

The lowest-order process for non-resonant diphoton production is very simple, as shown in Fig. 1(a). Despite this, the next-to-leading order (NLO) correction to this process is known to be very large [3, 4]. The large correction is predominantly due to the contribution from real radiation processes, illustrated in Figs. 1(b) to (d). While the gluon-radiation contribution from Fig. 1(b) should not be very large, the contribution from quark-radiation processes shown in Figs. 1(c) and (d) may become large due to the large gluon density inside protons. It is necessary to include these processes in order to provide a realistic simulation. However, available MC event generators consistently supporting these processes are limited because of a difficulty in treating the divergences associated with photon radiation. Although a recent release of SHERPA [5] seems to support such photon production, no other MC event generators are available as far as we know¹.

*E-mail: shigeru.odaka@kek.jp.

¹ A forthcoming release of HERWIG++ [6] may provide a consistent simulation as an NLO event generator [7].

Figure 1: Typical Feynman diagrams for non-resonant diphoton production at hadron collisions: (a) the lowest order, (b) a gluon radiation process, (c) a quark radiation process, and (d) another quark radiation process. Processes (b) and (c) have initial-state QCD divergences, while (d) has a final-state QED divergence.

In this report, we describe an MC event generator for non-resonant QED diphoton production in hadron collisions that we have developed, and discuss its predictions. The program has been developed in the framework of the GR@PPA event generator [8, 9] and supports the generation of radiative processes in Figs. 1(b) to (d), which include one additional jet (light quark or gluon) in the final state, together with the lowest-order process in Fig. 1(a). The matrix elements (ME) of these processes are generated using the GRACE system [10]. Though the event generator includes radiative processes, it is not fully including NLO corrections because non-divergent terms in soft/virtual corrections are yet to be included. In any case, the radiative processes have various divergences which we need to regularize. The initial-state strong-interaction (QCD) divergences can be regularized using a method that we have developed for weak-boson production processes, where divergent components are numerically subtracted from the matrix elements of radiative processes (the LLL subtraction) [11, 12, 13]. The subtracted components are restored by combining non-radiative processes to which a parton shower (PS) is applied. We can avoid the double-count problem by the subtraction and regularize the divergences as a result of the multiple radiation in PS.

The quark-radiation processes illustrated in Figs. 1(c) and (d) has not only an initial-state QCD divergence but also a QED divergence in the final state. We have extended the method for initial-state QCD divergences to this final-state QED divergence. The extension of the subtraction method is straightforward, while the preparation of an appropriate PS is not trivial since it has to support QED together with QCD. This PS has to be applied to the $qg \rightarrow \gamma q$ process to radiate photons from the final-state quark based on the collinear approximation (the fragmentation process). We have successfully developed such a PS on the basis of the QCD PS included in the GR@PPA 2.8 distribution².

Since parton showers are based on perturbative calculations, it is necessary to apply a certain cutoff to avoid collinear (small- Q^2) divergences. Further soft phenomena in QCD including non-perturbative effects are simulated by adopting appropriate models in general-purpose event generators, *e.g.*, PYTHIA [14]. However, such simulations are not available for QED photon radiation. Since we consider radiations from final-state partons, energetic photons visible in detectors can emerge even from very small- Q^2 branches. In order to simulate such small- Q^2 photon radiations, we have adopted a method employing a fragmentation function (FF). The PS supplemented with an FF-based simulation that we have developed has the capability of enforcing hard-photon radiation. This function dramatically improves the generation efficiency for the fragmentation process.

²The base release is the GR@PPA 2.8.3 update [9].

The generated events can be passed to PYTHIA [14] for simulating small- Q^2 QCD phenomena down to the hadron level. Hence, we can evaluate the effect of isolation requirements at the hadron level using the simulated events. Those events processed by PYTHIA can be fed to detector simulations of experiments. Further detailed studies will become possible with such simulations.

We sometimes find reports in which the detection efficiency and acceptance for diphoton measurements are evaluated by using event generators for the lowest-order process and the fragmentation process. Such evaluations are not self-consistent. Parton showers used in the simulation of the fragmentation process have an energy scale to be determined arbitrarily. The energy scale defines the maximum hardness of the radiation. The simulation results depend on this energy scale since those radiations exceeding the scale are ignored. Non-collinear contributions are also ignored. These ignored contributions may be small in many processes compared to the contributions taken into consideration. However, as we will show in this report, they may become comparable to the lowest-order contribution in diphoton production. It is necessary to include a simulation based on exact matrix elements for radiative processes in order to make a reliable evaluation.

The fragmentation process that we take into consideration in this report is the so-called "one-fragmentation" process. The "two-fragmentation" process in which two photons are radiated from final-state partons, for instance, from quarks in $gg \rightarrow q\bar{q}$, is not supported. Besides, the gluon-fusion process, $gg \rightarrow \gamma\gamma$, and its higher orders are not included in the present study.

We require a typical kinematical condition for the Higgs-boson search at the LHC through the present study because we are interested in its background; that is

$$\begin{aligned} p_T(\gamma_1) &\geq 40 \text{ GeV}/c, \quad p_T(\gamma_2) \geq 25 \text{ GeV}/c, \\ |\eta(\gamma)| &\leq 2.5, \quad \Delta R(\gamma\gamma) \geq 0.4 \\ 80 &\leq m_{\gamma\gamma} \leq 140 \text{ GeV}/c^2. \end{aligned} \quad (1)$$

We apply an asymmetric requirement to the transverse momenta (p_T) of photons with respect to the incident beam direction. The requirement on the pseudorapidity (η) is common to the two photons. In addition, though this is not effective for real diphoton events now we consider, we require a sufficient ΔR separation between the two photons, where ΔR is defined from the differences in the pseudorapidity (η) and azimuthal angle (ϕ) as $\Delta R^2 = \Delta\eta^2 + \Delta\phi^2$. Finally, the invariant mass of the two photons ($m_{\gamma\gamma}$) is restricted to the range that we are interested in. The simulations are carried out for the design condition of the LHC, proton-proton collisions at a center-of-mass (cm) energy of 14 TeV, with CTEQ6L1 [15] for the parton distribution function (PDF).

This report is organized as follows: the extension of the limited leading-log (LLL) subtraction method to the final-state QED divergence is described in Section 2, and the QCD/QED-mixed PS that we have developed is described in Section 3. The matching in the final-state QED radiation is discussed in Section 4. Results from a full simulation down to the hadron level are presented and the effect of a typical isolation requirement is discussed in Section 5. Physical results obtained from the full simulation are presented and discussed in Section 6, and the discussions are concluded in Section 7.

2 Final-state QED LLL subtraction

We approximate the final-state QED divergence in the matrix element for the $qg \rightarrow \gamma\gamma + q$ process as

$$\left| \mathcal{M}_{qg \rightarrow \gamma\gamma q}^{(\text{LLL}, \text{fin})}(\hat{s}, \hat{\Phi}_{\gamma\gamma q}) \right|^2 = \left| \mathcal{M}_{qg \rightarrow \gamma q}(\hat{s}_0, \hat{\Phi}_{\gamma q}) \right|^2 f_{q \rightarrow q\gamma}^{(\text{LL}, \text{fin})}(Q^2, z) g(\hat{s}, \hat{s}_0) \theta(\mu_{\text{LLL}}^2 - Q^2). \quad (2)$$

The leading-log (LL) radiation function can be given as

$$f_{q \rightarrow q\gamma}^{(\text{LL}, \text{fin})}(Q^2, z) = \frac{\alpha}{2\pi} \frac{16\pi^2}{Q^2} P_{q \rightarrow q\gamma}(z) \quad (3)$$

with the splitting function that is defined as

$$P_{q \rightarrow q\gamma}(z) = e_q^2 \frac{1+z^2}{1-z}, \quad (4)$$

where e_q is equal to $1/3$ for down-type quarks and $2/3$ for up-type quarks. The electromagnetic coupling, α , is assumed to be constant and equal to $1/132.51$, the value used for matrix-element calculations [16]. We evaluate Eq. (2) for two possible combinations of $q\text{-}\gamma$ pairs in the final state, and numerically subtract them from the matrix element of $qg \rightarrow \gamma\gamma q$, together with the LLL term for the initial-state QCD divergence [8]. The parameters Q^2 and z are defined by using the sum of the energy ($E_{q\gamma}$) and momentum ($p_{q\gamma}$) of the considered $q\text{-}\gamma$ pair. They are defined in the cm frame of the $qg \rightarrow \gamma\gamma q$ event as

$$Q^2 = E_{q\gamma}^2 - p_{q\gamma}^2, \quad (5)$$

and

$$z = \frac{p_L(E_{q\gamma} + p_{q\gamma}) + Q^2/2}{p_{q\gamma}(E_{q\gamma} + p_{q\gamma}) + Q^2}, \quad (6)$$

where p_L is the momentum component of the q in parallel to the summed momentum. Equation (6) is defined so that z should represent the momentum fraction at the infinite-momentum limit, $Q^2/p_{q\gamma}^2 \rightarrow 0$ [8].

Equation (3) is slightly different from the radiation function for the initial state [11]; z is absent in the denominator. This factor is included in the initial-state radiation function in order to take into account the change of the flux factor in the cross-section calculation, which is equal to the squared cm energy of the considered process. The relation between the squared cm energy of the non-radiative subprocess ($\hat{s}_0$) and that of the radiative process ($\hat{s}$) can be expressed as $\hat{s}_0 = z\hat{s}$ for initial-state radiations, whereas final-state radiations do not alter the cm energy at the limit $Q^2/p^2 \rightarrow 0$ where theories are usually discussed. Therefore, if we naively follow this argument, we should set $\hat{s}_0 = \hat{s}$ and $g(\hat{s}, \hat{s}_0) = 1$ in Eq. (2).

In our PS model, the kinematics of PS branches are so defined that the momentum is strictly conserved whereas the energy conservation is ignored [9]. The energy conservation is restored by increasing the initial-state parton momenta after completing the PS simulation. The mapping from a $qg \rightarrow \gamma\gamma q$ event to a non-radiative $qg \rightarrow \gamma q$ event, which is necessary for evaluating the LLL term in Eq. (2), has to strictly reverse this procedure in order to achieve a good matching. We define the quark momentum of the non-radiative process as the sum of the momenta of the quark and one of the two photons in the radiative process. Hence, for non-zero Q^2 , $\hat{s}_0$ is necessarily smaller than $\hat{s}$. Accordingly, the flux factor also changes in the final-state radiation. In order to take this change into account, we define the correction factor in Eq. (2) as

$$g(\hat{s}, \hat{s}_0) = \hat{s}/\hat{s}_0. \quad (7)$$

We note that this kind of correction, which is effective only at large Q^2 , strongly depends on the applied PS model. The correction in the above must be appropriate only for the PS model that we have adopted.

An event generator implementing the above subtraction has been developed in the framework of GR@PPA, and the generation was tested for the 14-TeV LHC condition. The energy scales were defined as [8]

$$\mu^2 = |\vec{p}_T(\gamma_1) - \vec{p}_T(\gamma_2)|^2/4, \quad (8)$$

where $\vec{p}_T(\gamma_i)$ denotes the transverse momentum vector of the two photons. This definition is equivalent to the ordinary definition, $\mu = p_T(\gamma)$, for $q\bar{q} \rightarrow \gamma\gamma$ events. We used the identical definition for the renormalization and factorization scales. The energy scale for the initial-state PS must be equal to the factorization scale in our method. Though it is not necessary, we adopted the same definition for the final-state PS. The energy scale to limit the LLL subtraction, μ_{LLL} in Eq. (2), must be equal to the energy scale of the final-state PS to be applied to the mapped non-radiative event [9]. We defined it to be equal to the p_T of the mapped $qg \rightarrow \gamma q$ event in the current study.

A result is shown in Fig. 2. We have plotted the distribution of ΔR between the photon and quark in the final state of the $qg \rightarrow \gamma\gamma + q$ events, where q represents any quark or anti-quark up to the b quark. We obtain two values since there are two photons in the final state. We take the smaller one as $\Delta R(\gamma\text{-jet})$. The constraint on the photons in Eq. (1) was required at the event generation. Parton showers are yet to be applied but the initial-state QCD LLL subtraction has been applied in this simulation. Therefore, the result is finite even though we have required practically nothing for the final-state quark. The quark is allowed to be very soft and out of the detection. This is why we

Figure 2: $\Delta R(\gamma\text{-jet})$ distribution of simulated $q\bar{q} \rightarrow \gamma\gamma + q$ events satisfying the kinematical condition in Eq. (1). The dotted histogram shows the distribution before applying the final-state QED LLL subtraction, where $\Delta R(\gamma\text{-jet}) > 0.1$ is required to cut off the divergence. The open circles and triangles show the distribution of positive- and negative-weight events, respectively, after the subtraction. The final result after applying the final-state subtraction is shown with filled circles. The initial-state QCD LLL subtraction has already been applied while parton showers are yet to be applied in this simulation.

denote the process as $q\bar{q} \rightarrow \gamma\gamma + q$ instead of $q\bar{q} \rightarrow \gamma\gamma q$. The distribution without the application of the final-state LLL subtraction is shown by the dotted histogram for comparison, in which we have applied a cutoff of $\Delta R(\gamma\text{-jet}) > 0.1$ in order to avoid the divergence at $\Delta R(\gamma\text{-jet}) = 0$.

Since the LLL subtraction is unphysical, we obtain negative-weight events as well as ordinary positive-weight events when we apply the subtraction. The event weights are always equal to +1 or -1 because BASES/SPRING [17, 18] automatically unweights the events. Therefore, we can obtain the desired distribution by subtracting the number of negative-weight events from that of positive-weight events in each histogram bin. The open circles and triangles in the figure show the distribution of positive- and negative-weight events, respectively, and the final distribution is shown by filled circles. We can see that the distributions after the subtraction converge to finite values as $\Delta R(\gamma\text{-jet}) \rightarrow 0$; not only does the final result converge to zero, but the distributions of positive- and negative-weight events individually converge to a finite value. These facts imply that the subtraction was performed properly, at least near the divergence limit. We have applied a very small cutoff, $\Delta R(\gamma\text{-jet}) > 0.01$, in the event generation for numerical stability. We can see that the effect of this cutoff is negligible.

The LLL subtraction is limited by the θ function in Eq. (2). A steep rise in the final distribution between $\Delta R(\gamma\text{-jet}) = 1.5$ and 2.0 corresponds to this limitation. The subtraction is not effective in the large $\Delta R(\gamma\text{-jet})$ region where events composed of two photons widely separated from the final-state quark exhibit. The distribution below the rise shows a non-logarithmic contribution remaining after the subtraction. The distribution of negative-weight events steeply decreases at large $\Delta R(\gamma\text{-jet})$ since they emerge only in the region where the subtraction is active. The negative-weight events at very large $\Delta R(\gamma\text{-jet})$ were produced by the initial-state QCD LLL subtraction.

3 Fragmentation process

The subtracted LL components have to be restored by non-radiative processes to which an appropriate PS is applied. The initial-state QCD LL components in $q\bar{q} \rightarrow \gamma\gamma + g$ and $qg \rightarrow \gamma\gamma + q$ can be restored with $q\bar{q} \rightarrow \gamma\gamma$ events to which an ordinary initial-state QCD PS is applied, as in the case of weak-boson production. On the other hand, the final-state QED LL components in $qg \rightarrow \gamma\gamma + q$ have to be restored with $qg \rightarrow \gamma q$ events to which a final-state PS including QED photon radiations is applied. We have developed such a PS.

3.1 QCD/QED-mixed PS

The implementation of parton showers is very simple. First of all, we define the Sudakov form factor which provides the probability that no branch happens between certain energy scales. It can be expressed by using the radiation probability, $\Gamma_i(Q^2)$, as

$$S(Q_1^2, Q_2^2) = \exp \left[- \int_{Q_1^2}^{Q_2^2} dQ^2 \sum_i \Gamma_i(Q^2) \right], \quad (9)$$

where the sum is taken over all relevant branch modes. The radiation probability can be obtained by integrating the splitting probability, $\Psi(Q^2, z)$, over the "momentum fraction" z as

$$\Gamma_i(Q^2) = \int_{z_{\min,i}}^{z_{\max,i}} \Psi_i(Q^2, z) dz. \quad (10)$$

Although the integration should be done from 0 to 1 ideally, we must frequently limit the range in order to regularize the divergences in the splitting probabilities. In our QCD PS [8], the splitting probability is approximated as

$$\Psi_i(Q^2, z) = \frac{1}{Q^2} \frac{\alpha_s(Q^2)}{2\pi} P_i(z) \quad (11)$$

by using the 1-loop QCD coupling, $\alpha_s(Q^2)$, and the leading-order splitting functions, $P_i(z)$.

In the actual implementation of PS, we first determine the Q^2 of a branch. Suppose that we have a branch at $Q^2 = Q_{\text{pre}}^2$. In the final-state (timelike) PS, the Q^2 of the next branch can be determined by solving the equation, $S(Q^2, Q_{\text{pre}}^2) = \eta$, by introducing a random number η which uniformly distributes in the range from 0 to 1. Once the Q^2 is determined, we can determine the branch mode i according to the radiation probability $\Gamma_i(Q^2)$, and then determine the z parameter in proportion to $\Psi_i(Q^2, z)$. The thus determined PS parameters, Q^2 and z , are converted to the momenta of participating partons based on a certain kinematics model. The model that we have adopted is discussed elsewhere [8, 9, 12].

We have extended the above discussion to QED. The Sudakov form factor and the radiation probability for QED radiations of quarks can be defined in the same way as in the above by using the QED splitting probability defined as

$$\Psi_{\text{QED}}(Q^2, z) = \frac{1}{Q^2} \frac{\alpha}{2\pi} P_{q \rightarrow q\gamma}(z). \quad (12)$$

The splitting function $P_{q \rightarrow q\gamma}(z)$ is defined in Eq. (4). We can consider this QED branch as one of the branch modes for defining the total Sudakov form factor in Eq. (9), and apply the same procedure for determining the PS parameters, Q^2 and z . Although it is not straightforward to solve the equation $S(Q^2, Q_{\text{pre}}^2) = \eta$ because the Q^2 dependence is different in the QCD and QED Sudakov form factors, we can obtain an accurate solution by performing an iteration. We found that if an appropriate iteration is applied we can achieve an accuracy better than 10^{-10} for the $S(Q^2, Q_{\text{pre}}^2)$ value with three or four iteration steps.

The above is a straightforward extension. The so-called "old model" of the PYTHIA PS [14], PYSHOW, employs a different method for generating QED branches. The Q^2 of the next branch is determined independently for possible QCD and QED branches, and the branch giving a larger Q^2 is taken as the next one. Although the implementation is very different, these two methods give an identical probability for QED radiation. When we have a branch at $Q^2 = Q_{\text{pre}}^2$, the probability that a

QED branch at $Q^2 = Q_{\text{QED}}^2$ is the next branch is $S(Q_{\text{QED}}^2, Q_{\text{pre}}^2)\Gamma_{\text{QED}}(Q_{\text{QED}}^2)$ for the both methods, where $S(Q_{\text{QED}}^2, Q_{\text{pre}}^2)$ is the total Sudakov form factor between the two energy scales and $\Gamma_{\text{QED}}(Q_{\text{QED}}^2)$ is the QED radiation probability at $Q^2 = Q_{\text{QED}}^2$. We have confirmed that these two methods give an identical result using our simulation program. Since the result is identical, it is better to use the PYSHOW method because it is faster; the iteration in the first method takes time.

A mixed PS which equally treats QCD and QED branches has been constructed by adding the above procedure to our PS. Incidentally, the implementation of PS is terminated at a certain Q^2 ($= Q_0^2$). We set $Q_0 = 5$ GeV in our PS. As has been discussed in the Introduction, hard photons can be radiated with even smaller Q^2 . In order to simulate such photon radiations, we add QED branches to partons remaining after the PS implementation according to the FF in Ref. [19]. We use the source code included in the DIPHOX 1.2 distribution [3]. Although this FF is based on the next-to-leading-log (NLL) approximation, and thus the gluons may radiate photons, we add the branches to the remaining quarks only. This FF program has two options. The difference between the two options predominantly results in different radiation probabilities from gluons. Since we do not consider the radiation from gluons, the difference is not significant in our application. We adopt the first option in the current study.

The FF gives us the probability of the photon radiation having a certain momentum fraction of x . The probability is integrated over the Q^2 range from a given energy scale (Q_{FF}^2) down to, in principle, $Q^2 = 0$. We set $Q_{\text{FF}}^2 = Q_0^2$. Though the FF gives us longitudinal momentum information, it does not provide any information on the transverse motion. However, this is not a serious problem in our application because the relevant Q^2 values are always small. Although it may be sufficient to add $q \rightarrow q\gamma$ branches without any transverse motion, we add a non-zero p_T to the branch products with respect to the parent-parton direction. The p_T value is randomly chosen according to a Gaussian distribution. We set the standard deviation of the Gaussian distribution to 1 GeV/ c tentatively in the present study.

3.2 Forced photon-radiation PS

A mixed PS supplemented with an FF radiation has been successfully constructed as described in the previous subsection. However, since the QED coupling is markedly smaller than the QCD coupling, it is not efficient to generate hard photons that we are interested in by using such a PS. It is desired to introduce a mechanism to enforce hard-photon radiation.

First of all, we consider the probability that the first QED branch is at $Q^2 = Q_{\text{QED}}^2$. The probability of there being a QCD branch at $Q^2 = Q_{\text{pre}}^2$ is $\Gamma_{\text{QCD}}(Q_{\text{pre}}^2)$. The probability of a QED branch at $Q^2 = Q_{\text{QED}}^2$ being the next branch is $S(Q_{\text{QED}}^2, Q_{\text{pre}}^2)\Gamma_{\text{QED}}(Q_{\text{QED}}^2)$, as described in the previous subsection. Of course, there should be no QED branch from a given PS energy scale (μ^2) down to Q_{pre}^2 . Therefore, the probability that we want to evaluate can be expressed as

$$P_{\text{QED}}^{(1)}(Q_{\text{QED}}^2, \mu^2) = S(Q_{\text{QED}}^2, \mu^2)\Gamma_{\text{QED}}(Q_{\text{QED}}^2) + \int_{Q_{\text{QED}}^2}^{\mu^2} dQ_{\text{pre}}^2 S_{\text{QED}}(Q_{\text{pre}}^2, \mu^2) \times \Gamma_{\text{QCD}}(Q_{\text{pre}}^2) \times S(Q_{\text{QED}}^2, Q_{\text{pre}}^2)\Gamma_{\text{QED}}(Q_{\text{QED}}^2). \quad (13)$$

We have added the first term in order to include the probability that the QED branch is the very first branch. Since $S(Q_1^2, Q_2^2) = S_{\text{QCD}}(Q_1^2, Q_2^2)S_{\text{QED}}(Q_1^2, Q_2^2)$, $S(Q_1^2, Q^2)S(Q^2, Q_2^2) = S(Q_1^2, Q_2^2)$ and

$$\frac{d}{dQ_2^2} S_i(Q_1^2, Q_2^2) = -S_i(Q_1^2, Q_2^2)\Gamma_i(Q_2^2), \quad (14)$$

the expression in Eq. (13) can be converted to

$$P_{\text{QED}}^{(1)}(Q_{\text{QED}}^2, \mu^2) = S_{\text{QED}}(Q_{\text{QED}}^2, \mu^2)\Gamma_{\text{QED}}(Q_{\text{QED}}^2). \quad (15)$$

This is the probability of finding the first QED branch at $Q^2 = Q_{\text{QED}}^2$ without taking QCD branches into consideration. Namely, the Q^2 of the first QED branch can be determined independently of QCD. We have verified this conclusion using our simulation.

A PS which enforces hard-photon radiation has been constructed based on the above discussion. We consider only one photon-radiation from each prompt quark produced by the hard interaction, and do not take into account the radiation from secondary quarks which are produced from gluon splitting. This assumption must be sufficient because the photon-radiation probability is very small. The FF photon radiation is also considered for the primary quarks only. In addition, we apply a constraint that the radiated photons always have large energy ($\geq E_{\min}$). The requirement of a hard-photon radiation results in certain constraints on random numbers used for executing the PS. The constraints determine the weight of the generated event. If this event weight is fed to the BASES/SPRING system appropriately, BASES/SPRING can automatically perform the cross-section integration and event generation according to the constraints that we require. The actual implementation of our PS is described in the following. The application of this PS improved the event-generation efficiency by a factor of 88 in the study to be described later.

Before starting the event generation, we evaluate the total FF-radiation probability for each quark flavor. We can evaluate it since Q_{FF} is always equal to the Q_0 of PS. When a quark to which we should apply the PS is selected, we can evaluate the total PS photon-radiation probability from the Sudakov form factor $S_{\text{QED}}(Q_0^2, \mu^2)$. The selection of the quark is trivial in the present study because each event includes only one quark in the final state. We estimate the total photon-radiation probability by adding the FF and PS probabilities, and take this probability as the base event-weight. Then, we determine whether the photon should be radiated from FF or PS according to the evaluated probabilities. If PS is chosen, we determine Q_{QED}^2 at which the QED branch should happen by solving the equation $S_{\text{QED}}(Q_{\text{QED}}^2, \mu^2) = \eta$. The random number η is constrained in the range to give a solution within $Q_0^2 < Q_{\text{QED}}^2 < \mu^2$, because this constraint is already taken into account in the event weight.

The QCD PS is applied as usual after the above procedure. During the evolution, when Q^2 for the next branch becomes smaller than Q_{QED}^2 , a QED branch is inserted instead of a QCD branch. Of course, the insertion is done only if the PS radiation is selected. Then, we determine the z parameter of the QED branch. We apply a hard-photon constraint here. Though the full three-dimensional kinematics is yet to be determined, the energy of the branching parton is available at this stage of the simulation. Thus, the requirement of $E_\gamma \geq E_{\min}$ can be converted to an allowed range of the z parameter. This constraint results in an additional event weight. The weight is zero if the energy of the branching parton is not large enough. After completing the determination of the z parameter, the QCD evolution is restarted by setting the maximum Q^2 to Q_{QED}^2 . After completing the PS simulation, a photon radiation is added according to the FF if the FF radiation is selected. The hard-photon requirement gives another event weight here because it constrains the allowed range of the x parameter in the FF.

The total event weight is evaluated as the product of all event weights, and passed to BASES/SPRING using the LabCut framework which is experimentally implemented in GR@PPA 2.8. Parton showers can be applied in both the integration and event-generation stages of BASES/SPRING in this framework. A cut can be applied to the events after the PS simulations. This framework is useful for generating events in which the kinematics of the particles of interest are strongly affected by PS, such as photon production with relatively small- p_T , because in principle we can apply a very loose condition at the hard-interaction generation. Incidentally, no cut is applied in the present study; the LabCut framework is used only for passing the event weight to BASES/SPRING. We have confirmed that the constructed PS (the forced PS) gives results identical to those from the mixed PS above the hard-photon requirement, $E_\gamma \geq E_{\min}$.

3.3 Corrections

The kinematics model which determines the relation between the PS parameters, Q^2 and z , and the parton momenta in the PS branch is described elsewhere [8, 9]. The model is designed so that the application of the final-state PS should never alter the momenta of the other particles in the final state. The application of a final-state PS necessarily increases the total energy in the final state since it makes on-shell partons develop into massive jets. The energy conservation is restored by increasing the initial-state parton momenta in our model. In the course of the present study, we found that this model is too naive to properly simulate the particle momenta inside jets. The implementation of PS is theoretically justified only at the collinear limit where the increase of the energy can be

ignored. The implementation may substantially depend on the applied model away from the limit. Our PS model increases the squared cm energy of the hard process, $\hat{s}$, and the cross sections of the hard processes that we are now interested in commonly decrease in proportion to $1/\hat{s}$. Hence, it must be natural to suppress the PS implementation in proportion to $1/\hat{s}$. In addition, since we increase the initial-state parton momenta, we should also take the change in the parton distribution function (PDF) into consideration.

In order to take these $\hat{s}$ effects into account, we apply a correction to the generated events as follows. The correction factors are evaluate as event weights. The weight relevant to the cross-section change is defined as

$$w_{\hat{s}} = \hat{s}/\hat{s}', \quad (16)$$

where $\hat{s}$ and $\hat{s}'$ represent the squared cm energy before and after the application of the final-state PS, respectively. The initial-state parton momenta are increased so that this increase should not alter the rapidity of the hard-interaction system. Hence, the momentum fraction of the initial-state partons is adjusted as $x'_i = \sqrt{\hat{s}'/\hat{s}}x_i$ where i represents two initial-state partons (1 or 2). The weight corresponding to the change of the parton density is defined as

$$w_{\text{PDF}} = \frac{f_1(x'_1, \mu_F^2)f_2(x'_2, \mu_F^2)}{f_1(x_1, \mu_F^2)f_2(x_2, \mu_F^2)}, \quad (17)$$

where $f_i(x_i, \mu_F^2)$ is the PDF for the parton i . We assume that the factorization scale, μ_F^2 , is unchanged. The total weight is evaluated as $w = w_{\hat{s}}w_{\text{PDF}}$. Since this weight is always smaller than one, we can apply a correction with a simple hit/miss rejection. If the event is rejected, the final-state PS is retried until the event is accepted. Therefore, this correction never alters the cross section of the event nor the momenta of final-state particles to which the PS is not applied. The correction solely alters the momentum distribution of particles inside PS and the resultant jet-mass distribution. Of course, the correction vanishes at the collinear limit.

3.4 Simulation result

The $\Delta R(\gamma\text{-jet})$ distribution of the fragmentation process simulated with the developed PS is shown in Fig. 3. The forced photon-radiation PS described in the above has been applied to the $qg \rightarrow \gamma q$ events generated in the LHC condition. The PS energy scale, μ_{FSR} , was chosen to be equal to the p_T of the generated events. The generation condition was sufficiently relaxed in order not to affect the final result. The initial-state PS is yet to be applied. We required a constraint of $E_\gamma \geq 20$ GeV in the forced PS. The kinematical condition in Eq. (1) was required after the PS simulation. Thus, the constraint in the forced PS does not affect the obtained result.

In order to derive the quantity $\Delta R(\gamma\text{-jet})$, we need to determine the momentum of the remnant jet in which the detected fragmentation photon is excluded. We define it from the initial-state parton momenta and the observed two photon momenta, without using the momenta of partons produced by PS. Although the obtained jet momentum is equal to the summed momentum of remnant partons in our simulation, this definition can be universally applied to other simulations in which the origin of final-state partons may be ambiguous. In any case, by using the obtained remnant-jet momentum, we can reconstruct a $qg \rightarrow \gamma\gamma + q$ event which can be compared with the parton-level $qg \rightarrow \gamma\gamma + q$ events generated according to the matrix elements. Since the jet mass of the remnant jet is ignored, the cm energy of the reconstructed $qg \rightarrow \gamma\gamma + q$ events is smaller than that of the simulated events. The energy conservation is restored by adjusting the initial-state parton momenta as is done in the PS application.

In Fig. 3, together with the total yield (plots), we have illustrated the PS (solid histogram) and FF (dashed histogram) contributions separately. The FF contribution is about 40% of the total, and is concentrated at small $\Delta R(\gamma\text{-jet})$. An unnatural bumpy structure at small $\Delta R(\gamma\text{-jet})$ evident in the total distribution suggests that the transverse motion added to FF branches must be too small. However, we do not need to be greatly concerned about this detail because $\Delta R(\gamma\text{-jet})$ is a quantity which is hard to accurately measure in actual experiments, especially at small $\Delta R(\gamma\text{-jet})$ where the fragmentation photon is confined inside a hadron jet. The tail in the FF contribution can be attributed to an effect of multiple QCD branches in PS. The distribution at large $\Delta R(\gamma\text{-jet})$ is dominated by

Figure 3: $\Delta R(\gamma\text{-jet})$ distribution of the fragmentation process. The forced PS with a constraint of $E_\gamma \geq 20$ GeV has been applied to the $qg \rightarrow \gamma q$ events generated in the LHC condition. The initial-state PS is not applied. The kinematical condition in Eq. (1) is required after the PS simulation. Together with the total yield (plots), the PS (solid histogram) and FF (dashed histogram) contributions are separately shown.

the PS contribution. The distribution is strongly suppressed above $\Delta R(\gamma\text{-jet}) = 1.5$ owing to the limitation by μ_{FSR} .

4 Matching test

The simulation of the $qg \rightarrow \gamma\gamma + q$ process is completed by adding the two simulations, the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ process and the fragmentation process. The matching between the two simulations can be rigorously tested at the parton level by using the distribution of a parameter $R_Q = Q/p_{T0}$. In the fragmentation events, Q is defined as the square root of the Q^2 parameter of the PS branch in which the fragmentation photon has been produced, and the p_T of the prompt photon is taken as p_{T0} . Thus, Q is not an observable quantity. Observable kinematical variables are affected by multiple QCD radiations in the fragmentation events. Such an alternation is a higher-order effect which is not taken into account in the parton-level $qg \rightarrow \gamma\gamma + q$ events. We can perform an unambiguous test at a common perturbation order by using the thus-defined quantity Q .

In our PS model, the parameter Q is assumed to be the invariant mass of the branch products. Hence, in the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ events, the quantity that should be compared with Q is the invariant mass of a γ - q pair. There are two possible values since two photons exist in the final state. We take the smaller one as Q , and take the p_T of the unpaired photon as p_{T0} . This p_T is the same as p_T of the non-radiative subprocess assumed in the LLL subtraction. Because we take the p_T of the non-radiative process as the final-state PS energy scale, μ_{FSR} , in the fragmentation events, and as the upper limit of the subtraction, μ_{LLL} , in the LLL-subtracted events by default, the LL component must be sharply shared between the two simulations at $R_Q = 1$ in the default setting.

The simulation results are shown in Fig. 4. The distributions were obtained with the simulations described in previous sections. The distribution of the fragmentation events is shown with a solid histogram, and that of the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ events with a dashed histogram. The dashed histogram at $R_Q < 1$ shows the remaining non-LL component in the $qg \rightarrow \gamma\gamma + q$ process. We set

Figure 4: R_Q distributions of simulated fragmentation events (solid histogram) and LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ events (dashed histogram). The sum of the two distributions is illustrated as a plot. See the text for the definition of the variable. A naive prediction from the $q\bar{q} \rightarrow \gamma\gamma + q$ ME with a constraint of $\Delta R(\gamma\text{-jet}) > 0.1$ is shown with a dotted histogram for comparison.

$Q = 0$ for FF branches. Hence, the FF-radiation events in the fragmentation process are concentrated in the first bin. The distribution for the fragmentation process that is extended up to $R_Q = 1$ is determined by PS branches.

The two simulation results have sharp edges at $R_Q = 1$ as expected. The sum of the two distributions is plotted with filled circles. We can see that the two simulations are connected smoothly at the boundary, and that the summed distribution has a natural shape without any remarkable discontinuity. The naive prediction from the $q\bar{q} \rightarrow \gamma\gamma + q$ ME with a constraint of $\Delta R(\gamma\text{-jet}) > 0.1$ is drawn with a dotted histogram for comparison. The summed distribution is in good agreement with this prediction down to $R_Q \sim 0.3$. The simulation result has to be suppressed with respect to the naive ME-prediction at small R_Q since the former is finite whereas the latter is divergent. We find that the suppression is effective only below $R_Q \sim 0.3$.

The agreement between the simulation and the ME prediction at $R_Q > 1$ is trivial since no subtraction is applied in this region. On the other hand, the agreement at $R_Q < 1$ is not trivial because the fragmentation result, which dominates the distribution in this region, depends on the applied corrections. The contribution from the non-LL component is also significant. The marked difference between the PS distribution and the ME prediction is completely supplemented by the non-LL contribution. We have confirmed that we always find a significant mismatch if any of the corrections described in previous sections is disregarded. Incidentally, the matching is not perfect. A small enhancement with respect to the ME prediction can be seen in the R_Q range from 0.3 to 0.7. The enhancement is at most 10% and far smaller than the higher-order QCD effects to be described later.

We set $\mu_{\text{FSR}} = \mu_{\text{LLL}} = p_{T0}$ in the above study. This choice is arbitrary. If the matching is perfect, the result should be unchanged even if we take other settings. We have tested the stability by changing the definition as $\mu = \mu_{\text{FSR}} = \mu_{\text{LLL}} = 0.5p_{T0}$ and $1.5p_{T0}$. The boundary in the R_Q distribution moves according to this change, as shown in Fig. 5. The sum of the distributions is over-plotted in Fig. 6 for the three settings. Despite the fact that the small enhancement at medium R_Q that we found in Fig. 4 produces a small mismatch in the case of $\mu = 0.5p_{T0}$, the three distributions are hard to

Figure 5: Energy-scale dependence of the R_Q distributions for the fragmentation process (a) and the LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ process (b). The results are shown for three settings: $\mu/p_{T0} = 0.5$ (dashed), 1.0 (solid) and 1.5 (dot-dashed), where $\mu = \mu_{\text{FSR}} = \mu_{\text{LLL}}$. The naive ME-prediction with $\Delta R(\gamma\text{--jet}) > 0.1$ is shown with a dotted histogram for comparison.

Figure 6: Energy-scale dependence of the R_Q distribution. The sum of the distributions in Fig. 5 is plotted for three settings for the energy scale: $\mu/p_{T0} = 0.5$ (open circles), 1.0 (filled circles) and 1.5 (open triangles). The dotted histogram shows the naive ME-prediction with $\Delta R(\gamma\text{--jet}) > 0.1$.

Figure 7: As for Fig. 4, but Q for the fragmentation events is defined as the invariant mass between the photon and quark ($m_{\gamma j}$) in the reconstructed parton-level $qg \rightarrow \gamma\gamma + q$ events.

distinguish from each other. Namely, the distribution is very stable against the change of the energy scale. The summed cross section is also stable within $\pm 6\%$.

The matching study described above has almost nothing to do with the kinematics model in the PS. The model only indirectly contributes to the tested distribution through the $\hat{s}$ corrections. Figure 7 shows another R_Q distribution, in which R_Q for the fragmentation events is defined using the reconstructed parton-level $qg \rightarrow \gamma\gamma + q$ events in the same way as in the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ events. Hence, the distribution should reflect the effect of the kinematics model. As we can see in Fig. 7, the change of the definition does not very significantly alter the distribution. The distribution for the LLL subtracted $qg \rightarrow \gamma\gamma + q$ is the same as that shown in Fig. 4. The FF radiations contribute to the distribution at small R_Q in this result.

The matching is still good, although we can see a significant enhancement in a wide range of R_Q with respect to the naive ME-prediction, and a slight discontinuity at $R_Q = 1$. These alternations can be attributed to the effects of QCD radiations preceding the QED radiation. The previously used Q must be identical to the γq invariant mass in our model if the QED branch is the first branch in PS. Preceding QCD branches smears this identity. The smearing results in the enhancement in the R_Q distribution because the distribution is a decreasing function of R_Q . Although they are not visible in Fig. 7, a very small but substantial amount of fragmentation events exhibit even at $R_Q > 1$ as a result of the smearing. This leakage causes the discontinuity at $R_Q = 1$. Since the smearing is a higher-order effect which is not included in the lowest-order $qg \rightarrow \gamma\gamma + q$ ME, these alternations should be considered as an advantage of our simulation. A similar enhancement in the weak-boson p_T spectrum at medium p_T is important to precisely reproduce the measurement data [13]. Note that the final-state QCD radiation effects are not taken into account in RESBOS and DIPHOX.

5 Full simulation and isolation cut

It is necessary in actual experiments to require an isolation condition in the identification of photons in order to reduce the huge background from hadron jets. It is difficult to reproduce the cuts applied by experiments with parton-level simulations. This is the main reason why hadron-level event generators are desired. Besides, if hadron-level events are generated consistently, the generated events can be

Figure 8: $\Delta R(\gamma\text{-jet})$ distribution of the fully simulated radiative processes. The fragmentation process (solid histogram) and the LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ process (dashed histogram) are combined to a smooth distribution (filled circles), which should be compared with the naive $q\bar{q} \rightarrow \gamma\gamma + q$ ME-prediction (dotted histogram). The dot-dashed histogram shows the distribution of $q\bar{q} \rightarrow \gamma\gamma + g$ events.

passed to detector simulations for more detailed studies.

In this section, we simulate a typical isolation condition by using events which have been simulated down to the hadron level. The event generation was carried out in the 14-TeV LHC condition separately for the fragmentation process and the other processes including the $q\bar{q} \rightarrow \gamma\gamma$, $q\bar{q} \rightarrow \gamma\gamma + g$, and $q\bar{q} \rightarrow \gamma\gamma + q$ processes, where q denotes any quark and anti-quark up to the b quark. The latter was generated simultaneously with the initial-state QCD and final-state QED LLL subtractions activated for radiative processes which include a jet (q or g) in the final state. The initial- and final-state parton showers (PS) were fully applied down to $Q_0 = 5.0$ GeV in both event generations, where a backward-evolution PS was used for the initial-state PS. The forced photon-radiation PS supplemented with the FF radiations was applied to the fragmentation process with a constraint of $E_\gamma \geq 15$ GeV, while the ordinary QCD PS was applied to the other processes.

The generated events were passed to PYTHIA 6.425 [14] in order to simulate further small- Q^2 phenomena down to the hadron level. The PYTHIA simulation was carried out with its default setting, except for `parp(67) = 1.0` and `parp(71) = 1.0`, as usual [8]. The kinematical cuts in Eq. (1) were applied to the hadron-level events. Although the PYTHIA simulation produces some soft photons, there is no ambiguity in the selection of the two candidate photons since the GR@PPA simulation produces only two photons. The event generation conditions were set very loose in order not to affect the final results. Note that the $g\bar{g} \rightarrow \gamma\gamma$ and two-fragmentation processes are not included in the current simulation.

The resultant $\Delta R(\gamma\text{-jet})$ distributions from the radiative processes are shown in Fig. 8. We obtain a smooth distribution plotted with filled circles by combining the distributions for the fragmentation process (solid histogram) and LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ process (dashed histogram). In the fragmentation process, $\Delta R(\gamma\text{-jet})$ has been derived from the parton-level $q\bar{q} \rightarrow \gamma\gamma + q$ events reconstructed as described in a previous section, while it has been derived directly from the generated parton-level event in the LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ process. The combined result should be compared with the naive $q\bar{q} \rightarrow \gamma\gamma + q$ ME-prediction shown with a dotted histogram, as in Fig. 2. We can see that they are in reasonable agreement in most of the regions, and that the divergence at $\Delta R(\gamma\text{-jet}) = 0$ in the

Figure 9: $\Delta R(\gamma\text{-jet})$ distribution of the radiative processes after the isolation cut is applied. The notation of the histograms and plot is the same as that in Fig. 8.

naive ME-prediction is naturally regularized in the combined result. We can also see a substantial enhancement of the combined result with respect to the naive ME-prediction in a wide range. This enhancement can be attributed to an effect of multiple QCD radiations in the final state. Although the distribution is finite, the events are strongly concentrated in a small $\Delta R(\gamma\text{-jet})$ region. The fragmentation photon is likely to be surrounded by hadrons when $\Delta R(\gamma\text{-jet})$ is small. Isolation requirements will suppress these events. On the other hand, isolation requirements will not be effective for other processes. The contribution from the $q\bar{q} \rightarrow \gamma\gamma + g$ process is illustrated with a dot-dashed histogram in Fig. 8. This distribution does not have any concentration at small $\Delta R(\gamma\text{-jet})$.

We impose an isolation condition by using a cone E_T which is defined at the hadron level as

$$E_{T,\text{iso}} = \sum_{\Delta R < R_{\text{iso}}} E_T, \quad (18)$$

where E_T is the transverse component of the particle energy with respect to the beam direction. The sum is taken over all particles inside a given ΔR cone around the photon, excluding the photon itself and neutrinos. We take as $R_{\text{iso}} = 0.4$ and require that $E_{T,\text{iso}} < 15$ GeV. The $\Delta R(\gamma\text{-jet})$ distribution after applying the cut is shown in Fig. 9. We can see that the isolation cut strongly suppresses the events in $\Delta R(\gamma\text{-jet}) \lesssim 0.4$, as expected. The events in this region are dominantly produced by the fragmentation process. About 40% of the events from the fragmentation process were rejected by the isolation cut. On the other hand, the cut has a small impact on the LLL-subtracted radiative processes. Although, about 5% of the events were rejected, including the contribution from $q\bar{q} \rightarrow \gamma\gamma$, the reduction in the cross section is only 1% because the nearly equal number of positive- and negative-weight events exhibited at small $\Delta R(\gamma\text{-jet})$ in the LLL-subtracted $qg \rightarrow \gamma\gamma + q$, as shown in Fig. 2.

Figure 10 shows the $E_{T,\text{iso}}$ distributions for the two photons in the fragmentation events. The distribution for the leading (highest- E_T) photon is shown with a dashed histogram, and that for the subleading photon with a solid histogram. The leading photon predominantly corresponds to the prompt photon produced by the $qg \rightarrow \gamma q$ interaction, and the subleading photons are mostly produced in the fragmentation of the quark. Parton showers produce low-energy partons in a wide area and the underlying-event simulation is activated in the PYTHIA simulation. These hadronic activities produce non-zero $E_{T,\text{iso}}$ even for the prompt photon by an accidental overlap. This contribution steeply decreases as $E_{T,\text{iso}}$ increases, as we can see in the dashed histogram in Fig. 10. In contrast,

Figure 10: $E_{T,\text{iso}}$ distributions for the selected two photons in the fragmentation events. The distribution for the leading (highest- E_T) photon is shown with a dashed histogram and that for the subleading photon with a solid histogram.

the distribution for the fragmentation photons shows a long tail extending to large $E_{T,\text{iso}}$. This tail corresponds to the hadronic activity produced in association with the photon, *i.e.*, the remnant jet.

Although small- $\Delta R(\gamma\text{-jet})$ events are strongly suppressed, the isolation cut does not produce a sharp edge in the $\Delta R(\gamma\text{-jet})$ distribution owing to a spread of the remnant jets. Figure 11 shows the p_T distribution of the remnant quark in the parton-level $q\bar{q} \rightarrow \gamma\gamma + q$ events reconstructed for the fragmentation events. The distribution for those events inside the parton-level isolation cone, $\Delta R(\gamma\text{-jet}) < 0.4$, are plotted. The solid and dashed histograms show the distribution after and before the isolation cut, respectively. The events with $p_T(\text{jet}) > 15 \text{ GeV}/c$ are likely to be rejected by the cut. However, the cut does not produce a sharp edge. On the other hand, a sharp edge should appear in this distribution and the distribution in Fig. 9 if we apply a similar cut at the parton level. This kind of smearing effect due to the final-state PS and hadronization cannot be evaluated without using simulations at the hadron level.

6 Combined results

We can obtain a consistent simulation result by combining the two simulations described in the previous section. Though we have not mentioned to the result from the $q\bar{q} \rightarrow \gamma\gamma$ process previously, this process is simultaneously simulated with the LLL-subtracted radiative processes. The initial-state PS applied to the $q\bar{q} \rightarrow \gamma\gamma$ events regularizes the initial-state LL components subtracted from the radiative processes.

Figure 12 shows the p_T distribution of the diphoton ($\gamma\gamma$) system from the combined simulation. The isolation cut described in the previous section has been applied to the simulated events selected with the kinematical condition in Eq. (1). In addition to the combined result (solid histogram), the distributions of subprocesses are separately shown. We can see that the p_T dependence is significantly different between the subprocesses. The integrated contribution from each subprocess is: 4.2 pb (23%) from $q\bar{q} \rightarrow \gamma\gamma$, 9.7 pb (54%) from the fragmentation, and 3.3 pb (18%) and 0.9 pb (5%) from the LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + q$ and $q\bar{q} \rightarrow \gamma\gamma + g$ processes, respectively. It is remarkable that the contribution from the lowest-order process, $q\bar{q} \rightarrow \gamma\gamma$, is smaller than 1/4 of the sum. Furthermore, the

Figure 11: p_T distribution of the quark in the parton-level $qg \rightarrow \gamma\gamma + q$ events reconstructed for the fragmentation events in $\Delta R(\gamma\text{-jet}) < 0.4$. The dashed histogram shows the distribution before the isolation cut and the solid histogram shows that after the cut, $E_{T,\text{iso}} < 15$ GeV.

Figure 12: p_T distribution of the diphoton ($\gamma\gamma$) system in the simulated events satisfying the kinematical condition in Eq. (1) and the isolation condition. The sum (solid histogram) is presented together with the distributions of the subprocesses: $q\bar{q} \rightarrow \gamma\gamma$ (dashed histogram with dots), the LLL subtracted $qg \rightarrow \gamma\gamma + q$ (dashed histogram) and $q\bar{q} \rightarrow \gamma\gamma + q$ (dot-dashed histogram), and the fragmentation process (dotted histogram). The result is compared with the predictions from RESBOS (filled circles) and DIPHOX (open circles). The DIPHOX prediction is presented at $p_T > 20$ GeV/ c only.

$p_T(\gamma\gamma)$ spectrum of $q\bar{q} \rightarrow \gamma\gamma$ is apparently different from the summed spectrum. In the weak-boson production processes which we have previously studied, the production is totally dominated by the lowest-order process at small p_T [13]. On the other hand, in the diphoton production, the lowest-order process is not dominant even at very small p_T ($\lesssim 10$ GeV/ c) as we can see in Fig. 12. Studies with the lowest-order process alone are not sufficient even if large- p_T contributions are intensively excluded. We can also see that simulations are not sufficient even if we include the fragmentation process in addition to the lowest-order process. The contribution from the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ process, which supplements the fragmentation process in the hard-radiation region, is nearly comparable to the lowest-order process, and has a $p_T(\gamma\gamma)$ spectrum remarkably different from the lowest-order and fragmentation processes.

It must be noted that the composition described in the above is not physically meaningful. The above result is obtained when we separate the soft and hard radiations at p_T of the $q\bar{q} \rightarrow \gamma\gamma$ or $qg \rightarrow \gamma q$ interaction. The composition changes if we adopt other definitions. Incidentally, it must also be noted that the fragmentation process is a part of the $qg \rightarrow \gamma\gamma + q$ process. The fragmentation process has been introduced to regularize the final-state divergence in $qg \rightarrow \gamma\gamma + q$. The sum of the fragmentation and LLL-subtracted $qg \rightarrow \gamma\gamma + q$ processes amounts to more than 70% of the total yield in our simulation. This fraction would not change dramatically even if we moved the separation criteria in a reasonable range. The domination of the $qg \rightarrow \gamma\gamma + q$ process is a characteristic feature of the diphoton production in hadron collisions, at least, at the LHC with a typical Higgs-search condition.

The simulated $p_T(\gamma\gamma)$ spectrum is compared with the prediction from RESBOS [4] in Fig. 12, for which we have used CTEQ6M [15] for PDF and required the same kinematical and isolation conditions. RESBOS provides an NLO prediction in which initial-state soft QCD radiations are resummed. It is considered to be most reliable at present as far as the $p_T(\gamma\gamma)$ distribution is concerned. Unfortunately, since the resummation can only predict inclusive properties, RESBOS cannot provide the hadron-level information. Thus, the selections are all applied at the parton level. The contribution from the $qg \rightarrow \gamma\gamma$ process is not included in the compared RESBOS prediction because this process is yet to be included in our simulation. The RESBOS prediction (filled circles) shown in Fig. 12 is smaller than the result presented in the original paper [4] because the $m_{\gamma\gamma}$ constraint in Eq. (1) is additionally required. We have confirmed that we can obtain a prediction close to the original result if the $m_{\gamma\gamma}$ constraint is removed. As we can see in Fig. 12, our simulation gives a substantially larger cross section than the RESBOS prediction although the overall tendency is consistent. The total cross section is 15.6 pb from RESBOS and 18.1 pb from our simulation.

The open circles in Fig. 12 show the prediction from DIPHOX [3] with the CTEQ6M PDF. DIPHOX is a full NLO calculation for diphoton production. The predictions are considered to be comparable with those from RESBOS. However, because soft QCD effects are not resummed, it cannot provide a continuous spectrum at small $p_T(\gamma\gamma)$. In Fig. 12, we have plotted the DIPHOX prediction in a relatively large $p_T(\gamma\gamma)$ region (> 20 GeV/ c) where we can obtain a continuous $p_T(\gamma\gamma)$ prediction. We have required the kinematical condition in Eq. (1) and the same isolation condition. The plotted prediction is the sum of the results for the "direct" process and the one-fragmentation process separately evaluated. We have used the LO prediction for the one-fragmentation process, and subtracted the $qg \rightarrow \gamma\gamma$ contribution from the direct process. The obtained DIPHOX prediction is continuously smaller than our simulation and the RESBOS prediction in the displayed $p_T(\gamma\gamma)$ range, although the difference becomes smaller as $p_T(\gamma\gamma)$ becomes larger. This $p_T(\gamma\gamma)$ behavior is reasonable because DIPHOX does not include initial-state radiation effects. The total cross section from this DIPHOX prediction is 13.7 pb.

Figure 13 compares the diphoton invariant-mass ($m_{\gamma\gamma}$) distribution obtained from our simulation (solid histogram) with those from RESBOS (filled circles) and DIPHOX (open circles). The results are almost comparable to each other, although there are substantial overall shifts between them and small differences in the $m_{\gamma\gamma}$ dependence. If we ignore the overall shifts, the DIPHOX prediction is closer to our simulation than RESBOS. The small- $m_{\gamma\gamma}$ fraction tends to be larger in our simulation and DIPHOX. Here, we have to remind that the isolation requirement in RESBOS is markedly different from that in DIPHOX and our simulation. Our simulation sums up the E_T of particles inside the isolation cone, $\Delta R < 0.4$, and rejects events if the summed E_T , $E_{T,\text{iso}}$, exceeds the threshold of 15 GeV. In principle, DIPHOX does the same rejection at the parton level. On the other hand,

Figure 13: Invariant-mass ($m_{\gamma\gamma}$) distribution of the diphoton system. Together with the combined result (solid histogram), the contribution from the fragmentation process (dotted histogram) and that from the other processes (dashed histogram) are separately presented. The result is compared with the predictions from RESBOS (filled circles) and DIPHOX (open circles).

although the selection condition is literally identical, RESBOS rejects the whole LL contribution when $\Delta R(\gamma\text{-jet}) < 0.4$, in order to regularize the final-state divergence. Events with $E_{T,\text{iso}} < 15$ GeV are allowed only for non-LL components. As we can see in Fig. 8, the fragmentation process that simulates the LL component in our simulation dominate the cross section inside the isolation cone. The contribution from the fragmentation process and that from the other processes are separately shown with dotted and dashed histograms, respectively, in Fig. 13. We can see that the fragmentation process shows a substantial enhancement at smaller $m_{\gamma\gamma}$ with respect to the others, suggesting that the small- $m_{\gamma\gamma}$ enhancement in DIPHOX and our simulation may be explained by the difference in the isolation requirement. The difference between our simulation and RESBOS, which we can see in Fig. 12, seems to support this argument; the difference is large in the region where the fragmentation contribution is large.

As a test, we have carried out a hybrid simulation in order to clarify the reason for the observed difference. In this simulation, we applied the kinematical cut and the isolation cut directly to the generated parton-level events in the LLL-subtracted radiative processes, without applying PS and the PYTHIA simulation. In the fragmentation process, only the final-state PS was applied to the generated events in order to reconstruct the parton-level $qg \rightarrow \gamma\gamma + q$ events. The kinematical cuts were applied to these parton-level events, and all events having $\Delta R(\gamma\text{-jet}) < 0.4$ were rejected in order to simulate the calculation in RESBOS. These are extensions of the simulations in the matching test. On the other hand, the full simulation down to the hadron level was applied to the lowest-order $q\bar{q} \rightarrow \gamma\gamma$ process in order to make the combined result comparable with the resummed calculation in RESBOS.

The combined $p_T(\gamma\gamma)$ distribution from the hybrid simulation is presented with a solid histogram in Fig. 14, to be compared with the RESBOS prediction plotted with filled circles. We can see a complete agreement between them over almost the entire $p_T(\gamma\gamma)$ region, except for a narrow region at small $p_T(\gamma\gamma)$. The total cross section from the hybrid simulation is 16.5 pb, which is only 6% larger than the RESBOS prediction. The agreement is remarkable but not surprising because the radiative processes which dominate the total cross section are evaluated at the tree level even in NLO calculations, such as RESBOS and DIPHOX. The contribution of non-divergent soft/virtual

Figure 14: p_T distribution of the diphoton ($\gamma\gamma$) system obtained from the hybrid simulation. The solid histogram shows the result from a RESBOS-style simulation in which all fragmentation events with $\Delta R(\gamma\text{-jet}) < 0.4$ are rejected. The dashed histogram has been obtained from a simulation in which the standard isolation cut, $E_{T,\text{iso}} < 15$ GeV, is applied at the parton level in all radiative processes. The results are compared with the RESBOS prediction shown with filled circles.

corrections which are missing in our simulation must be small, since the contribution of the lowest-order process to which the corrections are to be applied is small. The difference at small $p_T(\gamma\gamma)$ may have been caused by the difference between the PS and the resummation. In any case, the agreement implies that the calculations are reasonably carried out both in RESBOS and our simulation.

The dashed histogram in Fig. 14 shows the result from another hybrid simulation, in which we allowed those events with $E_{T,\text{iso}} < 15$ GeV in the fragmentation process. This change resulted in a step-like structure in the $p_T(\gamma\gamma)$ spectrum. The reason for this is quite simple. The p_T of the diphoton system is equal to the p_T of the remnant jet in the fragmentation process, and $E_{T,\text{iso}}$ is equal to this p_T if the remnant jet is inside the isolation cone. Therefore, the allowance of non-zero $E_{T,\text{iso}}$ produces an enhancement only at $p_T(\gamma\gamma) < 15$ GeV. This change increased the total cross section to 18.1 pb, which is in good agreement with the full simulation result. This step-like enhancement can be considered as the source of the difference between our simulation and RESBOS in Fig. 12. The enhancement must have been smeared by multiple QCD-radiation in PS and hadronization. Hence, the difference in Fig. 12 must be reasonable and shows the effects that are not supported in RESBOS.

We have carried out a study by using our custom-made PS in the above. We performed a similar study previously [20] by using the PYTHIA PS [14] for generating the fragmentation events. The matching properties were not fully satisfactory and the resultant diphoton-production cross section was smaller than the RESBOS prediction in that study. These were mainly caused by the fact that the photon yield from the PYTHIA PS was significantly smaller than that from our PS. The $\Delta R(\gamma\text{-jet})$ distributions obtained with the PYTHIA PS and our PS are compared in Fig. 15. We can see that the PYTHIA-PS predictions are almost always smaller than ours by about a factor of two. We do not understand the reason for this difference. In addition, though it may be too much detail, the drop in the first bin that we can see in the PYTHIA results is caused by the absence of small- Q^2 photon radiations ($Q < 1$ GeV). Such small- Q^2 radiations are simulated with the FF radiation in our PS.

Figure 15: $\Delta R(\gamma\text{-jet})$ distribution of the fragmentation process simulated with the PYTHIA PS and our PS in the standard setting. The distribution before and after the isolation cut is shown with a solid and dashed histograms, respectively, for the result with the PYTHIA PS. The corresponding distributions with our PS are plotted with filled circles and open circles, respectively.

7 Conclusion

We have developed an exclusive event generator for non-resonant QED diphoton ($\gamma\gamma$) production at hadron collisions, consistently including additional one-jet production. The $qg \rightarrow \gamma\gamma + q$ process to be included as a radiative process has a final-state QED divergence together with an initial-state QCD divergence. We have developed a final-state subtraction method by extending the method developed for initial-state QCD divergences (the LLL subtraction). The subtraction works as well as we expected. The differential cross section becomes finite after the subtraction and converges to zero at the limit where the original cross section diverges.

We have also developed a final-state parton shower (PS) for generating fragmentation events. The PS implements QED photon radiations as well as ordinary QCD radiations, and can enforce hard-photon radiation in order to improve the generation efficiency. Small- Q^2 photon radiations which are not covered by the PS are simulated by using a fragmentation function (FF). The divergent components in the final state which are subtracted from the radiative processes are restored with an appropriate regularization by applying this PS to $qg \rightarrow \gamma q$ events. The subtraction and regularization of initial-state QCD divergences are carried out in the same way as applied to weak-boson productions. The generated fragmentation events show a complete matching with the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ events.

A consistent simulation sample has been obtained by combining the fragmentation events with the $q\bar{q} \rightarrow \gamma\gamma$ and LLL-subtracted $q\bar{q} \rightarrow \gamma\gamma + g$ and $qg \rightarrow \gamma\gamma + q$ events simultaneously generated in GR@PPA. The event generation was tested for the LHC design condition, pp collisions at 14 TeV. A typical Higgs-boson search condition was required to the events simulated down to the hadron level. A typical isolation cut was also applied to the photons. We observed a reasonable suppression of the events in the collinear region, together with a visible smearing in physical distributions due to the application of PS and hadronization.

In our simulation, for which we have chosen all the energy scales to be equal to p_T of the non-radiative $q\bar{q} \rightarrow \gamma\gamma$ or $qg \rightarrow \gamma q$ events, the contribution from the lowest-order $q\bar{q} \rightarrow \gamma\gamma$ process is smaller

than 1/4 of the total yield. The contribution from the LLL-subtracted $qg \rightarrow \gamma\gamma + q$ process, which supplements the fragmentation process in hard-radiation regions, is comparable to it. A consistent inclusion of this process is necessary for reliable studies. If we combine the contributions from the fragmentation and LLL-subtracted $qg \rightarrow \gamma\gamma + q$ processes, the total $qg \rightarrow \gamma\gamma + q$ contribution amounts to more than 70%.

The combined simulation sample shows a behavior which reasonably agrees with the predictions from next-to-leading order (NLO) calculations by RESBOS and DIPHOX. Observed differences can be attributed to the different implementation of the isolation requirement, and higher-order QCD and hadronization effects which are not supported in NLO calculations. It must be noted that the two-fragmentation and $gg \rightarrow \gamma\gamma$ and their higher orders are yet to be included in our simulation.

Acknowledgments

This work has been carried out as an activity of the NLO Working Group, a collaboration between the Japanese ATLAS group and the numerical analysis group (Minami-Tateya group) at KEK. The authors wish to acknowledge useful discussions with the members.
